GEOLGY
AND
EARTH RESOURCES
OF
DELAWARE
INTRODUCTION

The purpose of this booklet is to discuss briefly the geological history of Delaware and to describe the earth resources of the State.

Delaware lies within two geologic provinces. The Appalachian Piedmont Province (northern 5% of the State) is composed of old, hard, crystalline rocks which are principally metamorphic. Building stone is the main earth resource of this region. The remaining 95% of the State is within the Atlantic Coastal Plain Province. In this Province the rocks are loose (unconsolidated) sediments of far younger age than the Piedmont rocks. Ground water is the principal earth resource; however, gravels, sands and clays of various types are abundantly available for exploitation.
GEOLOGIC HISTORY OF DELAWARE

Severe metamorphism has obscured the exact age relationships of the rocks of the Piedmont. This regional metamorphism is a product of crustal upheavals which built the Appalachian Mountain System. The major events in the evolution of these rocks occurred between 550 and 200 million years ago.

A great period of time, of which there is no record in Delaware, passed before the deposition of the oldest sediments of the Coastal Plain, the Potomac Formation, during the latter part of Early Cretaceous time, about 120 million years ago. Streams transported clays with interbedded sands from the Appalachians which lay to the northwest. This process continued into Late Cretaceous time and built a wedge with a thickness of about 4,000 feet in southern Delaware. A small unconformity, or period of nondeposition, separates the Potomac from the overlying Magothy Formation. The white sands and lignitic black slits of the Magothy form a distinctive marker indicating the transition from the older nonmarine sediments to the later marine deposits, from which they are separated by another small unconformity.

The sea now encroached deeply upon the land and remained over most of Delaware until at least Middle Eocene time; a sequence of varved marine sedimentary rocks was deposited essentially continuously during this interval. The oldest of these sediments from the Matawan Group, consisting of the Merchantville and Wennonah Formations. Neither of these persist as distinct entities far into the subsurface, and so the Matawan is relegated to formational status at depth, as is shown on the cross-section. Above the Matawan is the Monmouth sequence, also divisible into two formations near the surface, the Mount Laurel-Navesink and the Redbank, but comprising a single Monmouth Formation in the deeper subsurface. These marine Upper Cretaceous formations have been well exposed in the Chesapeake and Delaware Canal (Groot et al., 1954), where the Mount Laurel-Navesink is particularly fossiliferous (Richards and Shapiro, 1968). In the four marine formations, the sandy, quartzose Wennonah and Redbank represent periods of relative regression and the silty, glauconitic Merchantville and Mount Laurel-Navesink indicate transgression.

In the northern half of the Delaware Coastal Plain the time boundary between the Cretaceous and Tertiary (ca. 70 million years) is located within unit B. Farther south, in the subsurface, unit B, the upper part of the underlying Monmouth Formation, the Paleocene-to-Eocene Rancocas Formation, and unit C grade into a thick clay-silt mass termed unit A. The interrelationships of these rocks in the subsurface may be seen in the cross-section and are described by Jordan (1962). The subsurface Finey Point Formation, a quartzose sand which is the youngest of the Eocene, is, in part, the time equivalent of units A and C and is, in part, younger. All of these marine sediments are truncated by a major unconformity; no Oligocene deposits are present.

During the Miocene, the sea returned to cover the State, and deposition of sediment resumed. A sequence of three silts separated by two sand intervals forms most of the Chesapeake Group. Additional sands and silts are added toward the southeast where the Chesapeake attains its maximum thickness in Delaware of over 1,000 feet. Sands within the Chesapeake supply important amounts of water and are named, from oldest to youngest, the Cheswold, Frederica, Manokin, and Pocomoke aquifers. No sediments of proven Pleistocene age are known from the Coastal Plain, and the Chesapeake sediments are beveled by another major erosional unconformity.

During Pleistocene time, the advance and retreat of the continental glaciers brought about profound changes in sea level and in the streams which drained into Delaware. The Columbia Formation, consisting mostly of coarse sand with gravel, was deposited on the stream-channeled surface formed by the truncated edges of the Cretaceous and Tertiary beds, and thus is a sheet of irregular thickness overlying all of the Coastal Plain. During a later period of higher-than-present sea level, the sea reworked these continental deposits in the southern part of the State where they may be subdivided into the Omar and Beavard (and probably other) formations (Jordan, 1964). The general nature of the Columbia deposits is shown on the geologic map by patterns overlying the symbols of the older rocks; these are dashed where the character is mixed or presently in doubt.
MINERAL RESOURCES

Water Supplies

Water is the most important mineral resource in Delaware. In the Piedmont Province, most water is derived from streams, but in the Coastal Plain unconsolidated sedimentary rocks (sands and gravels) form the principal sources of water. The Delaware Geological Survey is engaged in a continuing program of refining our knowledge of the occurrence and hydraulic properties of the State's ground-water reservoirs. Some of these studies are done in cooperation with the U. S. Geological Survey, the Water Resources Center of the University of Delaware, and the Water and Air Resources Commission. The latter is mainly engaged in allocation of water supplies and pollution abatement.

Other Earth Resources

Numerous sand and gravel pits are located in Pleistocene sediments throughout the State. Not only is the sand and gravel valuable for use in construction, but preliminary testing shows that some sands may be suitable for glass sands, heavy minerals, or traction sands. Greensand (glaucnite) abounds in the Rancocas Formation in the Odessa-Middletown area. Greensand is a source of potash and has been used as a fertilizer and also in water softeners. Some of the greensand at Drawyers Creek near Odessa is 95% glaucnite.

Clay in Delaware has potential uses which have not been exploited. Research on clays by the Delaware Geological Survey and the U. S. Bureau of Mines indicates that virtually all of the Potomac Formation clay makes good face brick. Recent marsh deposits of clay near the Delaware River have potential use as sources of lightweight aggregate (fired, bloated clay fragments). Other clays are useful as raw material for ceramic tiles.

Other useful rocks and minerals in Delaware include: garnets for abrasives from the northern Piedmont area, kaolin for fine china from Piedmont pegmatite dikes, serpentine and gabbro for building stone from the Piedmont. Iron ore (limonite) is found as crusts in Pleistocene gravels. Feldspars and micas are found in Piedmont pegmatite dikes.

Mineral Production in Delaware

Mineral production in Delaware (clays, sand, gravel, and stone) exceeded $2.5 million officially in 1967 with a total tonnage in excess of 2 million short tons. Production is increasing over the years. From 1966 to 1967 there was an increase in tonnage of over 27% and an increase in value of more than 28%. Clays, in particular, have the potential for large increases in production and value because they are plentiful and largely unexploited.

Soils Maps

The water table is contoured on engineering soils maps published by the U. S. Geological Survey in cooperation with the Delaware Geological Survey and the State Highway Department.
